Key Points:

- The e-folding scale for fresh snow is found to be 11 ± 3 mm regardless of composition (water or carbon dioxide)
- In a snowpack, light propagation is dominated by scattering at grain surfaces instead of transmission through the ice itself

Abstract

The depth to which solar radiation can penetrate through ice is an important factor in understanding surface-atmosphere interactions for icy planetary surfaces. Mars hosts both water and carbon dioxide ice on the surface and in the subsurface. At high latitudes during autumn and winter carbon dioxide condenses to form the seasonal polar cap. This has been both modelled and observed to, in part, occur as snowfall. As snow accumulates, the thermal properties of the surface are changed, whether the underlying surface was rocky, regolith or a solid ice sheet. This results in a change (usually increase) in albedo, affecting the proportion of the incident solar energy reflected, or transmitted below the surface of the snow layer. The depth to which light can penetrate through this layer is an important parameter in heat transfer models for the Martian surface, and is often quantified using the e-folding scale. We present the first measurements of the e-folding scale in pure carbon dioxide snow for the wavelengths 300 nm to 1100 nm alongside new measurements of water snow.

Plain Language Summary

The solid-state greenhouse effect (SSGE) is similar to the climatic greenhouse effect. It occurs in solid materials that are translucent to visible light, but opaque in the infrared, such as ices. On Mars, snow and frosts form from both water and carbon dioxide ice. When the sun shines on the snow or frost, some light is diffusely reflected, some is transmitted through the snow grains, and some is absorbed by the ice. The proportion of light which travels through a material is dependent on its optical properties which are unique to its composition. Owing, however, to the nature of frost or snow being a very small, granular material, much of the light is scattered at the grain surfaces. In this study we measured the amount of light which can travel through a snow pack of a particular thickness for both water and carbon dioxide snows. This helps determine how much energy can be transported through the snow to the ground below, which warms up the underlying material. This means more accurate calculations can be made about the temperature profile of the Martian surface when covered in snow and frost, which gives insight into the different surface processes observed on Mars.

1. Introduction

Mars' northern permanent polar cap consists mostly of water ice, whereas the southern cap has a stable layer of carbon dioxide ice overlying the water ice. Carbon dioxide constitutes approximately 95% of the atmosphere of Mars, with water vapour constituting only 0.03% (Gillmann et al., 2009). During winter, the atmospheric pressure can drop by up to 25% (e.g. Leighton and Murray, 1966; Snyder, 1979), which equates to around 12 – 16% of the atmosphere by mass (Genova et al., 2016) due to the growth of the seasonal polar caps, which form expansive sheets of CO₂ ice. This ice can be emplaced by two different methods: precipitation or direct condensation.

Based on observations by the Mars Climate Sounder (MCS), Hayne et al. (2014) developed models which show snowfall contributes between 3% to 20% by mass to the southern seasonal ice deposits at latitudes ranging from 70° to 90° S, with the rest condensing directly from the atmosphere to the surface by radiative cooling. A number of previous studies had inferred CO₂ snow fall to be a common occurrence during the Martian winter, such as Titus et al. (2001), Hayne et al. (2012), Kuroda et al. (2013). In addition to this, Piqueux et al. (2016) reported widespread CO₂ frost deposits based on observations by the Mars Climate Sounder on board the Mars Reconnaissance Orbiter, significant due to the

latitudinal range over which the frosts were found, which reached into equatorial regions of low surface thermal conductivity and high elevation, such as around Tharsis Rise. This shows the CO₂ condensation-sublimation cycle affects the surface on a global scale, and is not just confined to high latitudes. These environments may be short lived – microphysical models suggest surface sintering could occur rapidly, removing particles less than 1 mm in a matter of days (Clark et al., 1983; Eluszkiewicz, 1993; Eluszkiewicz et al., 2005), although small-grained deposits are observed for longer periods, and so thought to be the locations of frequent snowfall (Hayne et al., 2012). Additionally, water snow fall and ice formation has been observed, in this instance directly, by the Phoenix Lander during late summer at its landing site (68.22N, 125.70 W), before being covered by the seasonal polar cap of CO₂ ice (e.g. Smith, et al., 2009; Cull et al., 2010).

The Phoenix Lander also observed night time water snow and ground frosts during late summer (Smith et al., 2009) at its landing site of 68.22° latitude in northern polar region (Arvidson et al., 2009; Smith et al., 2009). This increased in duration and quantity through to the end of Phoenix's operating period, and orbital measurements show this was followed by CO₂ ice coverage at approximately 30 cm deep (Cull et al., 2010), increasing in thickness poleward to around 1 m.

For the purposes of this investigation, 'snow' is used to describe fine-grained or porous ice deposits, of either H₂O or CO₂ ice. This could therefore be representative of both snowfall and surface frosts. Kaufmann and Hagermann (2015) and France et al. (2010) conducted experiments to determine the e-folding scale of water snow, and the effect of adding Mars simulant dust to the snow, using different methodologies, resulting in e-folding scales for pure water snow an order of magnitude different. What neither of these studies addressed, however, is how the presence of CO₂ snow, rather than water snow, affects the light penetration depth within Martian snow packs.

Here we investigate the e-folding scale of snow, composed of both H₂O and CO₂ ices, in order to determine how the presence of CO₂ snow affects surface processes which are driven by the interaction of solar irradiation with a surface. It is also important to have accurate and consistent water snow measurements, made under the same conditions, in order for direct comparisons to be made. Warren (1982) stressed the importance of understanding the optical properties of snow for calculating the radiation budget for snow-covered surfaces, in addition to applications for the remote sensing of snow-covered planetary surfaces. Ices behave differently to rocky or regolith-covered surfaces when exposed to solar irradiation because ices are translucent or transparent to visible and shorter wavelengths of light, whilst being opaque in the infrared. These properties contribute to the Solid State Greenhouse Effect (SSGE), first described by Matson and Brown (1989), although the concept that subsurface temperatures could be higher than the surface temperature in a terrestrial snow pack was reported first by Niederdorfer (1933). The extent of the SSGE is determined by multiple factors, including the optical properties of the icy material, grain size and shape, impurities, depth of ice, etc. One of the most important, but poorly understood, parameters when quantifying the SSGE is the e-folding scale (ζ), or penetration depth, of solar radiation within the sample (Möhlmann, 2010). Using the e-folding scale, the downward directed energy flux (F), as a function of ice thickness (x), is expressed as:

$$F(x) = e^{-x/\zeta} \quad (1)$$

Carbon dioxide ice has very different optical properties to water ice. The latter absorbs strongly throughout the infrared, whereas CO₂ ice absorbs strongly in only three narrow bands in the mid-infrared ($\lambda < 25 \mu\text{m}$), and two lattice absorptions in the far infrared ($\lambda > 25 \mu\text{m}$), with only very weak absorption in between these bands (Hansen, 1997). Solid CO₂ also exhibits a strong absorption continuum at ultraviolet wavelengths of 50 – 130 nm (Warren, 1986). It is therefore conceivable that there could be a considerable difference in the e-folding scale of snow made from these optically very different materials. The optical properties of solid CO₂ are wavelength dependent and, as a consequence, so are the albedo and emissivity. However, according to Warren et al. (1990), the most important factors controlling the radiative properties are grain size and dust contamination of the snow pack. The added complication when considering light penetration in snow over solid ice is the large number of scattering surfaces, resulting in light propagation being dependent upon both transmission through the ice and reflections at grain boundaries. This means that many other factors, such as grain size, shape, density of the snowpack, need to be considered in addition to the optical properties of the ice itself.

The combination of all of these factors shows the importance of broad wavelength range light penetration measurements, of both pure CO₂ and H₂O snow, in order to accurately determine the penetration depth of solar light. These measurements could lead to more accurate models of radiative transfer at the Martian surface, which could improve estimates of CO₂ snow deposition (such as those by Forget et al. (1998)), sub-snow surface temperatures and snow covered shallow sub-surface heat flow gradients, all of which lead to a better understanding of the dynamic Martian surface.

2. Methodology

2.1 Snow Preparation

CO₂ snow was made using an Air Liquide Snowpack maker, connected directly to a liquid CO₂ cylinder. The snow was then immersed in liquid nitrogen, which caused immediate disintegration of the snow pack, and ensured homogenous, fine grained snow, similar to the methodology of Kossacki et al. (1997). The suspension was then poured through a sieve to remove the snow from liquid nitrogen. At this point, the snow was around the temperature of liquid nitrogen, and was stored in sealed bags kept in an insulated polystyrene container in a freezer at 187 K for the duration of the experiments (around 2-3 hours in total), extracting only the quantity required for each experimental run. Due to the presence of some remaining liquid nitrogen in the container, the snow remained cold enough to prevent sintering, which would have caused the snow to clump and make it difficult to work with, invalidating the results.

Water snow was made by spraying deionised water into a dewar of liquid nitrogen. Once a sufficient amount of snow had formed in the bottom of the dewar the liquid nitrogen was then poured through a sieve (1.18 mm mesh size) to remove any larger ice chunks from the snow. As with the CO₂ snow, this was kept in sealed bags within an insulated box in the deep freezer, and used on the day of production, in order to avoid sintering. The resulting snow samples, both CO₂ and H₂O, can be seen in Figure 1.

Once made, the water snow was sieved using a range of standard sample sieve sizes, in order to determine if there was any grain size dependence on the e-folding scale. Note that, in this context, ‘grain size’ refers to conglomerates of small ice granules rather than grains of compact ice (see section 3). Figure 1 shows the typical structure of our snow. In order to investigate grain size dependence of light transmission through compact ice, a different production mechanism for the grains would have to be used. The sieves were pre-cooled, and

sieving was performed in a freezer, with the different snow samples immediately bagged and stored back in the freezer. The intention had been to repeat this process with CO₂ snow. However, due to the rapid sintering rates, and requirement for the sieves to be kept below the freezing point of CO₂, the process rendered the sample unusable for these experiments. Therefore, we conducted a grain size analysis on 3 separate samples of CO₂ snow prepared using identical methodology to that used in the experiments, and used the proportional grain sizes to be representative of each new snow batch made. The proportional grain size distribution within each CO₂ snow pack sieved and weighed can be seen in Figure 2.

Both the CO₂ and H₂O snow experiments were undertaken in an argon-filled chamber, which is first cooled with liquid nitrogen (shown in Figure 4). This both reduced the sublimation rate of the CO₂ ice, and minimised water frost deposition on both the sample and the glass plate the sample is placed on.

Throughout these experiments, all samples are freshly prepared and stored for as short a time as possible, under conditions which minimise the possibility of sintering. This is particularly problematic with CO₂ snow, due to its low freezing point. When a substance condenses as a fluffy, fine grained deposit such as snow, sintering occurs in order to achieve the preferred thermodynamic state of minimum surface energy (Eluszkiewicz, 1993). Therefore, sintering results in grain growth and densification. As a consequence, the optical path length through the grains increases, thus reducing the number of scattering surfaces over a fixed volume. This would therefore have a significant impact on the e-folding scale of the material. This process can be seen in Figure 3, through leaving a batch of snow to sinter for increasing amounts of time, in a sealed container placed in the freezer at 187 K. In the final/lower-right image, the residual grain outlines can still be seen, where the individual grains have grown via vapour diffusion, and eventually joined up.

2.2 Experimental setup

The experimental setup is shown in Figure 4. The sample was irradiated using a full spectrum solar simulator (LS1000R3, Solar Light Company), with the beam directed via a mirror to penetrate the sample perpendicular to the surface of sample, which was scraped flat and smooth. The transmitted irradiation was then measured using a pyranometer (CS300, Campbell Scientific Ltd.) sensitive to wavelengths from 300 nm to 1100 nm (absolute accuracy $\pm 5\%$ for daily total radiation). Prior to the experiment commencement the beam intensity was measured with the pyranometer to monitor consistency, although it is important to note that our e-folding scale measurements are independent of total irradiance.

The experiment chamber and contents (including glass plate which the sample was placed on and the scraper), were pre-cooled prior to experiment commencement by use of the cooled argon. If these were cooled in the freezer separately, whilst they may be colder, they would immediately frost up when removed from the freezer and placed in the chamber. Some lumps of CO₂ snow were also placed in the bottom of the chamber, away from the pyranometer, in order to facilitate more efficient cooling at this initial stage. These had completely sublimated by the time experiments were under way. There was no specific temperature control other than to cool the system as much as possible.

2.3 Experimental Procedure

Reliable albedo measurements for thin samples are difficult to obtain, and are often of poor accuracy due to the measurements being influenced more by the albedo of the underlying surface than the sample being measured (Wiscombe and Warren, 1980).

Consequently, in order to avoid these additional uncertainties, a minimum thickness of 5 mm of snow is used in all of these experiments. This is then taken as the zero point for the calculation of the e-folding scale; with all measurements normalised accordingly. This is consistent with the methods of Kaufmann and Hagermann (2015), who used a minimum snow thickness of 5 mm for their measurements.

A series of copper rings 86 mm in diameter (painted black on the inside to prevent internal reflections) were used to contain the snow samples at set thicknesses. This ensured consistent volumes of snow, and made reducing the thickness of the snow pack for consecutive measurements quick and accurate. The sample was placed inside the chamber, the solar simulator lamp turned on and first light intensity measurement taken. The shutter was closed on the solar lamp between measurements in order to minimise sublimation and sintering. For water snow, four measurements are made per snow thickness, one in the centre and three further measurements at different locations in the sample offset from the centre. This is in order to reduce the effect of any slight inhomogeneities present within the sample. However, due to the rapid sintering rate of CO₂ snow just one measurement per snow thickness could be made.

The top copper ring was then removed and the snow sample gently scraped smooth along the level of the underlying copper ring with the flat edge of a plastic spatula to the next required thickness. This was conducted whilst inside the chamber and flooded with cooled argon. The lamp was then unshuttered in order to take the next measurement, and the process repeated as swiftly as possible. Bohren and Barkstrom (1974) suggested that light transmission experiments in snow should be made using a sample container whose diameter is at least twice the maximum sample thickness, in order for any interference from the walls on the sample to be negligible. Therefore, the maximum snow thickness used for any measurements was 35 mm (to ensure this effect is minimised completely). In addition, like Kaufmann and Hagermann (2015), it was found that the larger the snow sample, the greater the errors induced from a number of sources. Therefore, in order to minimise the error of sample thickness measurement, maximise the amount of energy analysed by the pyranometer, and minimise errors introduced by secondary reflections from and diffuse scattering within the sample, measurements were mainly taken over 15 mm, and the results exclusively calculated over this range. Measurements were taken through samples at 15 mm, 10 mm and 5 mm for both water and carbon dioxide snows.

Each sample was weighed prior to irradiation commencement, and so the initial density of each snow pack has been calculated for both H₂O and CO₂ snow. It was not possible to weigh the samples in between irradiation events at each thickness, as this would have exposed the samples to warmer temperatures and humidity, accelerating sintering rates and increasing the amount of water frost contamination in CO₂ snow samples (an example of which can be seen in Figure 5), and melting in the water snow samples. It was particularly important to prevent melting of the water snow, as not only does liquid water have a different refractive index to ice, water pooling in-between snow grains would essentially increase the optical path length by joining up grains with an optically similar material (ice/air boundary compared to ice/water boundary) and so will cause much less scattering, and therefore less attenuation, than without the liquid phase. Efforts were made at each reduction of snow thickness to only scrape the surface level without compacting the snow pack, although it is acknowledged that some small amount of compaction may have occurred.

Cooled argon continuously flowed into the chamber in an attempt to mitigate the formation of water frost on both the samples of CO₂ snow, and on the glass plate suspending the samples above the pyranometer.

4. Results

Light intensity measurements made through CO₂ and H₂O snow samples of different thicknesses were conducted using an identical experimental set up, and the results used to calculate the e-folding scale, or penetration depth, of each material. These were made using a broad wavelength range across the visible spectrum (300 – 1100 nm). Figure 6 shows how the e-folding scale varies with density. A practice run was made to test the initial experimental setup and, for the sake of completeness, is also plotted and denoted by an orange cross. Several alterations to the setup were made based on this measurement, which included improvements to reduce air leakage into the chamber, and flooding the chamber with cooled argon to prevent the formation of water frost.

The e-folding scale is calculated from the raw light intensity measurements by first adjusting the data for the 5 mm measurement to be taken as the zero depth to remove the effect of albedo (as previously discussed). All data are then normalized accordingly, and by rearranging equation 1, the e-folding scale (ζ) is then calculated. The full datasets of raw light intensity measurements for both CO₂ and H₂O snows are available in the supplementary material provided alongside this manuscript. As water snow measurements have 4 data points for each sample thickness, the raw light intensity readings were averaged for each snow depth prior to calculating the e-folding scale. The results are plotted in Figure 6, where it can be seen that there is a very weak correlation of higher e-folding scale with increased density, although this is less evident in the H₂O snow data than in CO₂ snow.

The density of CO₂ snow on Mars has been constrained to $910 \text{ kgm}^{-3} \pm 230 \text{ kgm}^{-3}$ based on data from the Mars Orbiter Laser Altimeter on the Mars Global Surveyor (Smith et al., 2001), a range which is covered by our measurements. Our results suggest that the e-folding scale does not vary significantly through the density range. This seems to be consistent with previous studies measuring other optical properties of water snow; Bohren and Beshta (1979) found that, if grain size was kept constant, then there was no significant change in albedo with compaction (an average 1 percentage point decrease in albedo for compacted snow, not significant at the 90% confidence level).

The mean e-folding scale of water snow was found to be 11.24 mm, and 11.25 mm for CO₂ snow (excluding the practice run). This result was unexpected given that the optical properties of these two materials are quite different. Additionally, the reported e-folding scale for H₂O and CO₂ slab ice has quite a large variation: the measurements made by Chinnery et al. (2018) report the e-folding scale of CO₂ slab ice varied from 35 mm to 65 mm depending upon the state of the ice sample, such as the extent of cracking or ‘milkyiness’ of the ice; no broad spectrum penetration depth measurements for water ice have been found in the literature, however those made at discrete wavelength ranges show orders of magnitude differences based on wavelength: e-folding scales decrease sharply from 24 m at $\lambda=470 \text{ nm}$, to 8 m at $\lambda=600 \text{ nm}$, 2 m at $\lambda=700 \text{ nm}$, $\lambda=0.05 \text{ m}$ at 1000 nm, and $\lambda=0.006 \text{ m}$ at 1400 nm (Perovich, 1996). However, we propose that for small grain sizes such as snow, such a small amount of light transmission occurs through the ice grains that the material properties have a negligible effect and light transmission is dominated by scattering/multiple reflections between grains. This suggests that at these very small scales, grain morphology and the number of scattering surfaces is more important than snow composition.

This interpretation is further supported by the data represented in Figure 7. Artificial water snow can be kept pure and stable much more easily than CO₂ snow, and so grain size dependence was tested using only water snow. If this had been attempted with CO₂ snow then

sintering and H₂O frost accumulation would have occurred during the multiple sieving steps required, rendering the samples unusable. The snow was prepared and sieved as outlined in the methodology section, and light transmission was measured on discrete grain size ranges. It can be seen that there is no discernible trend linking e-folding scale with grain sizes at this small scale, although it should be noted that scatter in the data increased with decreasing snow grain size.

Upon close scrutiny of the water snow, which had been sieved to discrete grain sizes, it could be seen that the ‘grains’ actually appeared to consist of clumps of even smaller granules. It is therefore perhaps more accurate to describe the grain size ranges by using only the upper boundary. Whilst a finer meshed sieve was also used to define the lower limit of the grain size range, it cannot be conclusively said that the smallest individual grains are larger than this, only that the smallest clumps of grains are at least this size. This can be seen in Figure 8, for the grain size range 0.71 – 0.85 mm.

Based on these observations, it is impossible to tell whether these granular conglomerates behave optically as one unit, or as the individual constituents, scattering light at each internal surface. It would be reasonable to assume a range of behaviour with regard to this, depending on the extent to which the conglomerate grain has fused together. It should, however, be noted that the snow used for the actual measurements was kept at consistently lower temperatures than the sample shown here, which would have warmed, and therefore likely sintered, to a greater extent during the process of photographing it. This suggests one contributing factor as to why, in the data presented here (Figure 7), we observe no significant trend between the penetration depth and grain size, despite theoretically being expected. In addition to this, Chinnery et al. (2018) found the e-folding scale of CO₂ slab ice to vary from around 35 mm to 65 mm, the upper limit being for near-pristine slabs, and the lower for highly cracked imperfect ice, reducing the effective ‘grain size’ or path length between cracks. It seems most likely, due to the difficulties in constraining the grain sizes by sieving, that the large range of actual grain sizes make it difficult to discern a trend in the data.

Beaglehole, et al. (1998) conducted light transmission experiments in naturally formed Antarctic snow, and modelled their results using spherical snow particles and two flux theory, which showed that whilst the absorption coefficient should scale with relative density, the scattering coefficient should scale inversely with grain size. This explains our observation of little density dependence in the e-folding scale results from these measurements of snow grains <1.18 mm, and why is it the same regardless of composition, as little absorption is occurring. However, it also implies that there should be strong grain size dependence. We suggest that this trend is obscured by uncertainties in determining the minimum grain size range for each snow sample, as discussed above. Combined with the relatively small range of grain sizes analysed, this results in inherent errors which are larger than the amplitude of any trend which could have been recorded. A more extensive range of measurements covering a much larger range of ice grain sizes, formed using compact ice, would be required to determine the underlying cause of these observations.

5. Discussion

The snow used for the e-folding scale experiments by Kaufmann and Hagermann (2015) was made by an industrial snow cannon, and was later found to contain some contaminants. This is acceptable for determining the effect of dust contamination, as it was the only variable in the system, but not so accurate for determining the e-folding scale of pure water snow. We believe Kaufmann & Hagermann’s value of 5.4 ± 1 mm to be too low

because the effect of contaminants generally decreases the e-folding scale. France et al. (2010) also conducted light intensity measurements through pure and dust contaminated snow packs. Conversely, they generated their water snow by spraying pure water into a bath of liquid nitrogen, similar to the methodology used in our study presented here, meaning the snow was free of contaminants. However, the samples were then left to sinter for 24 hours at 253 K, which would result in a not insignificant degree of sintering. Sintering is the process of grains both growing and in part fusing together followed by snow pack densification, thus increasing the path length which light propagates through the snow. This goes some way to explaining why their e-folding scale is an order of magnitude greater than that measured by Kaufmann and Hagermann (2015). By contrast, the samples for our measurements were always freshly prepared – and did not contain any impurities. It should also be noted that France et al. (2010) used discrete wavelengths from 400 nm to 700 nm, whereas the measurements presented here are across the broader wavelength range of the pyranometer (300 nm – 1100 nm), which could also explain some discrepancy in the results. This is demonstrated by the vast range of e-folding scales of sea ice reported by Perovich (1996) and discrete wavelength ranges, from 24 m at $\lambda = 470$ nm, decreasing dramatically to 5 cm at $\lambda = 1000$ nm.

A sophisticated model of solar radiation penetration in CO₂ ice was created by Pilorget et al. (2011) which combined both radiative and conductive heat transfer methods with the optical properties of carbon dioxide ice. The findings presented in this manuscript are consistent in principle with these model results, in that small grains of CO₂ ice, of a size classed as ‘snow’ throughout this study, do now allow enough light to penetrate through a layer to allow for any significant heating of the underlying regolith. What this study did not provide, however, were the resultant penetration depths for CO₂ ice in the different scenarios modelled.

The implications of such a small e-folding scale for fine-grained ices are that if there is even a small amount of snow cover on top of the seasonal ice slab, which it is reasonable to suggest could remain suitably cold so as to not cause rapid sintering of the snow, then light penetration into the ice sheet could be dramatically dampened. This would hamper the formation of araneiforms, for example, which only occur when adequate energy can be transmitted through the ice to the underlying regolith. This is in order to heat the regolith sufficiently to cause basal sublimation which leads to CO₂ jetting, as per the CO₂ jetting model (Kieffer, 2000, 2007; Kieffer, et al., 2006; etc.). Perovich (1996) states that, on Earth, a 25 cm covering of snow on top of an ice sheet would reduce light transmittance to less than 1%. Whilst this would be a very large amount of CO₂ snow to accumulate on Mars, the simulations run by Colaprete (2002) indicate that 0.75 g of CO₂ snow could be deposited per cm² during one hour of snowfall beneath the CO₂ clouds forming the polar hood. If using a snow density of 910 kgm⁻³ (Smith et al., 2001), this equates to 8.2 mm thick deposit of snow, and given the e-folding depth of 11.2 mm \pm 3 mm, even at these lesser snow depths a significant reduction in radiation intensity will occur, potentially halting the CO₂ jetting process whilst the snow remains in situ. This would not even necessarily require snow fall to emplace fine grained ice deposits. One of the issues raised by Pilorget et al. (2011) was that CO₂ jetting was observed on dune slopes but not on the flat areas between dunes. They suggested that venting was still occurring in these areas, but the underlying regolith on the flat areas has a higher albedo than that of the dune material, and so made it harder to observe. In addition to the issue of detection, it could also be speculated that if fine-grained icy debris ejected from the vents on the dune slopes were carried downslope (either simply by gravity, or wind-blown) and deposited around the foot of the dune, that the presence of even a very

thin layer of granular ice on top of the slab ice, combined with the higher albedo regolith (therefore less absorbing) could be enough to suppress jetting activity.

CO₂ sublimation processes have also been linked to the formation of gullies in the absence of liquid water (e.g. Hoffman, 2002; Cedillo-Flores, et al. 2011; Pilorget and Forget, 2015; Vincendon, 2015). These are mainly found in the 30°- 60° latitude range in both hemispheres, and activity has been linked to the time when seasonal CO₂ frost is present on the surface and beginning to defrost (Pilorget and Forget, 2015). In a series of laboratory experiments, Sylvest, et al. (2018) condensed CO₂ frost onto JSC Mars-1 simulant regolith, held at angles ranging from 10° through to the angle of repose, in order to investigate gully formation when exposed to incident radiation. They found that the CO₂ formed as fine grained deposits on the surface, and between the regolith grains. Significant thicknesses of CO₂ frost (up to several centimetres) can accumulate on pole-facing slopes even at mid-latitudes, even though these are illuminated by the sun (Schorghofer and Edgett, 2006).

An e-folding scale of only 1.1 cm in snow would mean that the underlying material, be it regolith or ice, is largely unaffected by insolation - and thus might remain colder than anticipated. Lower subsurface temperatures reduce gas movement through the pores in a sediment, affecting both the subsurface-atmosphere exchange of CO₂ and the likelihood of sediment movement to be triggered by CO₂ sublimation. Lower subsurface temperatures also affect the sublimation of other volatiles potentially present in the subsurface, such as water, increasing the survival time of any subsurface water ice deposits.

6. Conclusions

The e-folding scale of fresh, un-sintered water snow and carbon dioxide snow have been measured across the wavelengths 300 nm to 1100 nm and found to be $\zeta = 11 \text{ mm} \pm 3 \text{ mm}$, regardless of composition, for grains <1.18 mm. This has applications for use in radiative transfer models applied to Mars and other icy surfaces in the solar system where fine grained ice or snow is present. Although snow may only fall at isolated locations and times of year, there is a wide-spread, low latitude and year round frost cycle for which this work is also applicable. Whilst water and carbon dioxide ices have different optical properties, and in massive, or slab ice form, they have different e-folding scales, for grain sizes <1.18 mm, the large amount of scattering surfaces based on the grain morphology is a more important factor than ice composition, making internal reflections within the snowpack the dominant light transfer mechanism over transmission through the ice grains. As snow sinters and compacts over time, light propagation through the ice will transition from being dominated by scattering, to an increase in propagation through the ice until it e-folding scales of slab ice are more applicable, which differ based on composition. This shows that, whilst it is important to be able to define the composition of solid ice to determine the thermal regime of the surface, if there is snow cover, the composition of that snow does not affect the penetration depth of broad wavelength solar radiation. This could simplify the incorporation of surface CO₂ snow cover into models, as this had previously been approximated to either exhibit the same behaviour as CO₂ clouds, as in Forget et al. (1998) or has been calculated theoretically for a given wavelength and single grain size, using CO₂ optical properties in a combination Mie theory and the Delta-Eddington method for scattering in a snowpack (e.g. Pilorget et al., 2011). In order to understand the transition from light transmission in snow to that in slab ice, a more extensive range of measurements covering a much larger range of ice grain sizes would be required. Results from this would also give insights on how snow which has begun sintering would behave, with grain sizes increasing until slab ice is formed.

Whilst this has obvious implications for the Martian surface (where both water and carbon dioxide snow and granular ice has been detected) wherever ices are present on a surface, such as comets or icy moons, with incident solar irradiation a solid state greenhouse will be induced, and so the e-folding scale of that ice will be an important parameter to define.

Acknowledgments, Samples, and Data

The authors would like to thank Ganna Portyankina and two further anonymous reviewers for their comments and suggestions which have greatly improved this manuscript. This work was funded by STFC under grant no. ST/N50421X/1 with additional support from grant no. ST/L000776/1. Access to the full dataset generated in these experiments can be found in the supporting documentation.

Figure 1. Freshly made CO₂ snow (left) and H₂O snow (right). Upon visual inspection it is difficult to tell the two materials apart. Both ices, when formed using our method, consist of fine granular material which appears white and fluffy. The scale on the ruler in both images is in millimetres.

Figure 2. Representative grain size distribution in CO₂ snow packs using our methodology. Note that even a large a snow ‘grain’ can consist of hundreds of minuscule ice granules only a few 10s of μm in diameter.

Figure 3. From top left to bottom right: Freshly made CO₂ snow; CO₂ snow left in the freezer at 187 K for 7 days; CO₂ snow left in freezer for 12 days; CO₂ snow left in freezer for 17 days. Over time the very fine grains of snow in the first image gradually grow in size and joint up until forming solid sheets of ice several centimetres in length, in the 17 day image (bottom right).

Figure 4. Schematic of experimental set-up for CO₂ ice e-folding scale measurements (top), and photograph of the same set up in the lab (bottom).

Figure 5. Water frost forming on larger grains of translucent carbon dioxide ice when exposed to air.

Figure 6. E-folding scale results plotted with snow pack starting density. The data point denoted by the orange cross was an initial run with CO₂ snow, which enabled the experimental set up to be refined. This practice run was excluded from further analyses of this data. Errors in the density measurements (horizontal error bars) are calculated based on measuring equipment tolerances, and the vertical errors for the e-folding scale account for both equipment tolerances and potential human error introduced when scraping each ice thickness flat.

Figure 7. The e-folding scale results for water snow, dependent on snow grain size. Snow grains larger than 1.18 mm were deemed too big to be defined as ‘snow’, and so are not used for these analyses. Horizontal error bars simply denote the range of grain sizes contained within that sample. Vertical errors here are based on the experimental error, including device tolerance and human error.

Figure 8. Water snow sieved to grainsizes between 0.71 mm - 0.85 mm. On initial inspection the grain size range appears entirely reasonable (left). However, when inspected at closer range (right), noting the scale shown on both images is in millimetres, clusters of grains much smaller than 0.71 mm can be seen clustered together forming conglomerates which appear to fall within the desired grain size range.
